Abstract

A Long Short-Term Memory (LSTM) network is a type of recurrent neural network architecture which has recently obtained strong results on a variety of sequence modeling tasks. The only underlying LSTM structure that has been explored so far is a linear chain. ever, natural language exhibits syntactic properties that would naturally combine words to phrases. We introduce the Tree-LSTM, a generalization of LSTMs to tree-structured network topologies. Tree-LSTMs outperform all existing systems and strong LSTM baselines on two tasks: predicting the semantic relatedness of two sentences (SemEval 2014, Task 1) and sentiment classification (Stanford Sentiment Treebank).

1 Introduction

Most models for distributed representations of phrases and sentences—that is, models where realvalued vectors are used to represent meaning—fall into one of three classes: bag-of-words models, sequence models, and tree-structured models. In bag-of-words models, phrase and sentence representations are independent of word order; for example, they can be generated by averaging constituent word representations (Landauer and Dumais, 1997; Foltz et al., 1998). In contrast, sequence models construct sentence representations as an order-sensitive function of the sequence of tokens (Elman, 1990; Mikolov, 2012). Finally, in tree-structured models, each phrase and sentence representation is composed from its constituent subphrases following a given syntactic structure over the words and phrases in the sentence (Goller and Kuchler, 1996; Socher et al., 2011).

In order to produce sentence representations that fully capture the semantics of natural lan-

Figure 1: **Top:** A chain-structured LSTM network. **Bottom:** A tree-structured LSTM network with arbitrary branching factor.

guage, order-insensitive models are insufficient due to their inability to account for differences in meaning as a result of differences in word order or syntactic structure (e.g., "cats climb trees" vs. "trees climb cats"). We therefore turn to ordersensitive sequential or tree-structured models. In particular, tree-structured models are a linguistically attractive option due to their relation to syntactic interpretations of sentence structure. A natural question, then, is the following: to what extent (if at all) can we do better with tree-structured models as opposed to sequential models for sentence representation? In this paper, we work towards addressing this question by directly comparing a type of sequential model that has recently been used to achieve state-of-the-art results in several NLP tasks against its tree-structured generalization.

Due to their capability for processing arbitrarylength sequences, recurrent neural networks (RNNs) are a natural choice for sequence modeling tasks. Recently, RNNs with Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997) have re-emerged as a popular architecture due to their effectiveness at capturing long-term dependencies. LSTM networks, which we review in Sec. 2, have been successfully applied to a variety of sequence modeling and prediction tasks, notably machine translation (Bahdanau et al., 2014; Sutskever et al., 2014), speech recognition (Graves et al., 2013), image caption generation (Vinyals et al., 2014), and program execution (Zaremba and Sutskever, 2014).

In this paper, we introduce a generalization of the standard LSTM architecture to tree-structured network topologies and show its superiority for representing sentence meaning over a sequential LSTM. While the standard LSTM composes its hidden state from the input at the current time step and the hidden state of the LSTM unit in the previous time step, the tree-structured LSTM, or Tree-LSTM, composes its state from an input vector and the hidden states of arbitrarily many child units. The standard LSTM can then be considered a special case of the Tree-LSTM where each internal node has exactly one child.

We evaluate the Tree-LSTM architecture on two tasks: semantic relatedness prediction on sentence pairs and sentiment classification of sentences drawn from movie reviews.

2 Long Short-Term Memory Networks

2.1 Overview

Recurrent neural networks (RNNs) are able to process input sequences of arbitrary length via the recursive application of a transition function on a hidden state vector h_t . At each time step t, the hidden state h_t is a function of the input vector x_t that the network receives at time t and its previous hidden state h_{t-1} . For example, the input vector x_t could be a vector representation of the t-th word in body of text (Elman, 1990; Mikolov, 2012). The hidden state $h_t \in \mathbb{R}^d$ can be interpreted as a d-dimensional distributed representation of the sequence of tokens observed up to time t.

Commonly, the RNN transition function is an affine transformation followed by a pointwise non-linearity such as the hyperbolic tangent function:

$$h_t = \tanh\left(Wx_t + Uh_{t-1} + b\right).$$

Unfortunately, a problem with RNNs with transi-

tion functions of this form is that during training, components of the gradient vector can grow or decay exponentially over long sequences (Hochreiter, 1998; Bengio et al., 1994). This problem with *exploding* or *vanishing gradients* makes it difficult for the RNN model to learn long-distance correlations in a sequence.

The LSTM architecture (Hochreiter and Schmidhuber, 1997) addresses this problem of learning long-term dependencies by introducing a *memory cell* that is able to preserve state over long periods of time. While numerous LSTM variants have been described, here we describe the version used by Zaremba and Sutskever (2014).

We define the LSTM unit at each time step t to be a collection of vectors in \mathbb{R}^d : an input gate i_t , a forget gate f_t , an output gate o_t , a memory cell c_t and a hidden state h_t . The entries of the gating vectors i_t , f_t and o_t are in [0,1]. We refer to d as the memory dimension of the LSTM. The LSTM transition equations are the following:

$$i_{t} = \sigma \left(W^{(i)} x_{t} + U^{(i)} h_{t-1} + b^{(i)} \right),$$

$$f_{t} = \sigma \left(W^{(f)} x_{t} + U^{(f)} h_{t-1} + b^{(f)} \right),$$

$$o_{t} = \sigma \left(W^{(o)} x_{t} + U^{(o)} h_{t-1} + b^{(o)} \right),$$

$$u_{t} = \tanh \left(W^{(u)} x_{t} + U^{(u)} h_{t-1} + b^{(u)} \right),$$

$$c_{t} = i_{t} \odot u_{t} + f_{t} \odot c_{t-1},$$

$$h_{t} = o_{t} \odot \tanh(c_{t}),$$
(1)

where x_t is the input at the current time step, σ denotes the logistic sigmoid function and \odot denotes elementwise multiplication. Intuitively, the forget gate controls the amount of which each unit of the memory cell is erased, the input gate controls how much each unit is updated, and the output gate controls the exposure of the internal memory state. The hidden state vector in an LSTM unit is therefore a gated, partial view of the state of the unit's internal memory cell. Since the value of the gating variables vary for each vector element, the model can learn to represent information over multiple time scales.

2.2 Variants

Two commonly-used variants of the basic LSTM architecture are the Bidirectional LSTM and the Multilayer LSTM (also known as the *stacked* or *deep* LSTM).

Bidirectional LSTM. A Bidirectional LSTM (Graves et al., 2013) consists of two LSTMs that are run in parallel: one on the input sequence and the other on the reverse of the input sequence. At each time step, the hidden state of the Bidirectional LSTM is the concatenation of the forward and backward hidden states. This setup allows the hidden state to capture both past and future information.

Multilayer LSTM. In Multilayer LSTM architectures, the hidden state of an LSTM unit in layer ℓ is used as input to the LSTM unit in layer $\ell+1$ in the same time step (Graves et al., 2013; Sutskever et al., 2014; Zaremba and Sutskever, 2014). Here, the idea is to let the higher layers capture longer-term dependencies of the input sequence.

These two variants can be combined as a Multilayer Bidirectional LSTM (Graves et al., 2013).

3 Tree-Structured LSTMs

A limitation of the LSTM architectures described in the previous section is that they only allow for strictly sequential information propagation. Here, we propose two natural extensions to the basic LSTM architecture: the *Child-Sum Tree-LSTM* and the *N-ary Tree-LSTM*. Both variants allow for richer network topologies where each LSTM unit is able to incorporate information from multiple child units.

As in standard LSTM units, each Tree-LSTM unit contains input and output gates i_j and o_j , a memory cell c_j and hidden state h_j . The difference between the standard LSTM unit and Tree-LSTM units is that gating vectors and memory cell updates are dependent on the states of possibly many child units. Additionally, instead of a single forget gate, the Tree-LSTM unit contains one forget gate f_{jk} for each child k. This allows the Tree-LSTM unit to selectively incorporate information from each child. For example, a Tree-LSTM model can learn to emphasize semantic heads in a semantic relatedness task, or it can learn to preserve the representation of sentiment-rich children for sentiment classification.

As with the standard LSTM, each Tree-LSTM unit takes an input vector x_j . In our applications, each x_j is a vector representation of a word in a sentence. The input word at each node depends on the tree structure used for the network. In a Tree-LSTM over a dependency tree, each node in the tree takes the vector corresponding to the

Figure 2: Composing the memory cell c_1 and hidden state h_1 of a Tree-LSTM unit with two children (subscripts 2 and 3). Labeled edges correspond to gating by the indicated gating vector, with dependencies omitted for compactness.

head word as input. In a Tree-LSTM over a constituency tree, the leaf nodes take the corresponding word vectors as input.

3.1 Child-Sum Tree-LSTMs

Given a tree, let C(j) denote the set of children of node j. The Child-Sum Tree-LSTM transition equations are the following:

$$\tilde{h}_j = \sum_{k \in C(j)} h_k,\tag{2}$$

$$i_j = \sigma \left(W^{(i)} x_j + U^{(i)} \tilde{h}_j + b^{(i)} \right),$$
 (3)

$$f_{jk} = \sigma \left(W^{(f)} x_j + U^{(f)} h_k + b^{(f)} \right),$$
 (4)

$$o_j = \sigma \left(W^{(o)} x_j + U^{(o)} \tilde{h}_j + b^{(o)} \right),$$
 (5)

$$u_j = \tanh\left(W^{(u)}x_j + U^{(u)}\tilde{h}_j + b^{(u)}\right),$$
 (6)

$$c_j = i_j \odot u_j + \sum_{k \in C(j)} f_{jk} \odot c_k, \tag{7}$$

$$h_i = o_i \odot \tanh(c_i), \tag{8}$$

where in Eq. 4, $k \in C(j)$.

Intuitively, we can interpret each parameter matrix in these equations as encoding correlations between the component vectors of the Tree-LSTM unit, the input x_j , and the hidden states h_k of the unit's children. For example, in a dependency tree application, the model can learn parameters $W^{(i)}$ such that the components of the input gate i_j have values close to 1 (*i.e.*, "open") when a semantically important content word (such as a verb) is given as input, and values close to 0 (*i.e.*, "closed") when the input is a relatively unimportant word (such as a determiner).

Since the Child-Sum Tree-LSTM unit conditions its components on the sum of child hidden states h_k , it is well-suited for trees with high branching factor or whose children are unordered. For example, it is a good choice for dependency trees, where the number of dependents of a head can be highly variable.

3.2 N-ary Tree-LSTMs

The N-ary Tree-LSTM can be used on tree structures where the branching factor is at most N and where children are ordered, *i.e.*, they can be indexed from 1 to N. For any node j, write the hidden state and memory cell of its kth child as h_{jk} and c_{jk} respectively. The N-ary Tree-LSTM transition equations are the following:

$$i_{j} = \sigma \left(W^{(i)} x_{j} + \sum_{k=1}^{N} U_{k}^{(i)} h_{jk} + b^{(i)} \right), \quad (9)$$

$$f_{jk} = \sigma \left(W^{(f)} x_{j} + \sum_{\ell=1}^{N} U_{k\ell}^{(f)} h_{j\ell} + b^{(f)} \right), \quad (10)$$

$$o_{j} = \sigma \left(W^{(o)} x_{j} + \sum_{k=1}^{N} U_{k}^{(o)} h_{jk} + b^{(o)} \right), \quad (11)$$

$$u_{j} = \tanh \left(W^{(u)} x_{j} + \sum_{k=1}^{N} U_{k}^{(u)} h_{jk} + b^{(u)} \right), \quad (12)$$

$$c_j = i_j \odot u_j + \sum_{k=1}^N f_{jk} \odot c_{jk}, \tag{13}$$

(12)

$$h_j = o_j \odot \tanh(c_j), \tag{14}$$

where in Eq. 10, k = 1, 2, ..., N.

The introduction of separate parameter matrices for each child k allows the N-ary Tree-LSTM model to learn more fine-grained conditioning on the states of a unit's children than the Child-Sum Tree-LSTM. Consider, for example, a constituency tree application where the left child of a node corresponds to a noun phrase, and the right child to a verb phrase. Suppose that in this case it is advantageous to emphasize the verb phrase in the representation. Then the $U_{k\ell}^{(f)}$ parameters can be trained such that the components of f_{j1} are close to 0 (i.e., "forget"), while the components of f_{j2} are close to 1 (i.e., "preserve").

Note that in general the number of parameters scales as $O(N^2|h|^2)$; this architecture is therefore only practical for small N. We can naturally apply

Binary Tree-LSTM units to binarized constituency trees since left and right child nodes are distinguished.

When the tree is simply a chain, both Eqs. 2–8 and Eqs. 9–14 reduce to the standard LSTM transitions, Eqs. 1.

4 Models

We now describe two specific models that apply the Tree-LSTM architectures described in the previous section.

4.1 Tree-LSTM Classification

In this setting, we wish to predict labels \hat{y} from a discrete set of classes \mathcal{Y} for some subset of nodes in a tree. For example, the label for a node in a parse tree could correspond to some property of the phrase spanned by that node.

At each node j, the label \hat{y}_j given the inputs $\{x\}_j$ observed at nodes in the subtree rooted at j is predicted by a softmax classifier that takes the hidden state h_j at the node as input:

$$\hat{p}_{\theta}(y \mid \{x\}_j) = \operatorname{softmax} \left(W^{(s)} h_j + b^{(s)} \right),$$
$$\hat{y}_j = \arg \max_{y} \hat{p}_{\theta} \left(y \mid \{x\}_j \right).$$

The cost function is the negative log-likelihood of the true class labels $y^{(k)}$ at each labeled node:

$$J(\theta) = -\frac{1}{m} \sum_{k=1}^{m} \log \hat{p}_{\theta} \left(y^{(k)} \mid \{x\}^{(k)} \right) + \frac{\lambda}{2} \|\theta\|_{2}^{2},$$

where m is the number of labeled nodes in the training set and the superscript k indicates the kth labeled node.

4.2 Semantic Relatedness of Sentence Pairs

Given a sentence pair, we wish to predict a real-valued similarity score in some range [1,K], where K>1 is an integer. The sequence $\{1,2,\ldots,K\}$ is some ordinal scale of similarity, where higher scores indicate greater degrees of similarity, and we allow real-valued scores to account for ground-truth ratings that are an average over the evaluations of several human annotators.

We first produce sentence representations h_L and h_R for each sentence in the pair using a Tree-LSTM model over each sentence's parse tree. Given these sentence representations, we predict the similarity score \hat{y} using a neural network that

considers both the distance and angle between the pair (h_L, h_R) :

$$h_{\times} = h_{L} \odot h_{R},$$

$$h_{+} = |h_{L} - h_{R}|,$$

$$h_{s} = \sigma \left(W^{(\times)}h_{\times} + W^{(+)}h_{+} + b^{(h)}\right),$$

$$\hat{p}_{\theta} = \operatorname{softmax}\left(W^{(p)}h_{s} + b^{(p)}\right),$$

$$\hat{y} = r^{T}\hat{p}_{\theta},$$
(15)

where $r^T = [1 \ 2 \ \dots \ K]$ and the absolute value function is applied elementwise.

We want the expected rating under the predicted distribution \hat{p}_{θ} given model parameters θ to be close to the gold rating $y \in [1, K]$: $\hat{y} = r^T \hat{p}_{\theta} \approx y$. We therefore define a sparse target distribution p that satisfies $y = r^T p$:

$$p_i = \begin{cases} y - \lfloor y \rfloor, & i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & i = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases}$$

for $1 \le i \le K$. The cost function is the regularized KL-divergence between p and \hat{p}_{θ} :

$$J(\theta) = \frac{1}{m} \sum_{k=1}^{m} \text{KL} \Big(p^{(k)} \, \Big\| \, \hat{p}_{\theta}^{(k)} \Big) + \frac{\lambda}{2} \|\theta\|_{2}^{2},$$

where m is the number of training pairs and the superscript k indicates the kth sentence pair.

5 Experiments

We evaluate our Tree-LSTM architectures on two tasks: (1) sentiment classification of sentences sampled from movie reviews and (2) predicting the semantic relatedness of sentence pairs.

In comparing our Tree-LSTMs against sequential LSTMs, we control for the number of LSTM parameters by varying the dimensionality of the hidden states². Details for each model variant are summarized in Table 1.

	Relatedness		Sentiment	
LSTM Variant	d	$ \theta $	d	$ \theta $
Standard	150	203,400	168	315,347
Bidirectional	150	203,400	168	315,347
2-layer	108	203,472	120	318,720
Bidirectional 2-layer	108	203,472	120	318,720
Constituency Tree	142	205,190	150	316,800
Dependency Tree	150	203,400	_	_

Table 1: Memory dimensions d and composition function parameter counts $|\theta|$ for each LSTM variant that we evaluate.

5.1 Sentiment Classification

In this task, we predict the sentiment of sentences sampled from movie reviews. We use the Stanford Sentiment Treebank (SST) (Socher et al., 2013). There are two subtasks: binary classification of sentences, and fine-grained classification over five classes: very negative, negative, neutral, positive, and very positive. We use the standard train/dev/test splits of 6920/872/1821 for the binary classification subtask and 8544/1101/2210 for the fine-grained classification subtask (there are fewer examples for the binary subtask since neutral sentences are excluded).

The sentiment label at each node is predicted using the a softmax classifier, as described in Sec. 4.1. We use Binary Tree-LSTMs (Sec. 3.2) structured according to the constituency parse trees provided with the dataset. For the sequential LSTM models, we predict the sentiment for each phrase using the final hidden state after the entire phrase has been processed. We train the sequential LSTMs on all labeled spans in the training set.

5.2 Semantic Relatedness

For a given pair of sentences, the semantic relatedness task is to predict a human-generated rating of the similarity of the two sentences in meaning.

We use the Sentences Involving Compositional Knowledge (SICK) dataset (Marelli et al., 2014), consisting of 9927 sentence pairs in a 4500/500/4927 train/dev/test split. The sentences are derived from existing image and video description datasets. Each sentence pair is annotated with a relatedness score $y \in [1,5]$, with 1 indicating that the two sentences are completely unrelated, and 5 indicating that the two sentences are very related. Each label is the average of 10 ratings assigned by different human annotators.

Here, we use the similarity model described in

¹In the subsequent experiments, we found that optimizing this "classification" objective yielded better performance than a mean squared error objective.

²For our Bidirectional LSTMs, the parameters of the forward and backward transition functions are shared. In our experiments, this achieved superior performance to Bidirectional LSTMs with untied weights and the same number of parameters (and therefore smaller hidden vector dimensionality)

Method	Fine-grained	Binary
RAE (Socher et al., 2013)	43.2	82.4
MV-RNN (Socher et al., 2013)	44.4	82.9
RNTN (Socher et al., 2013)	45.7	85.4
DCNN (Blunsom et al., 2014)	48.5	86.8
Paragraph-Vec (Le and Mikolov, 2014)	48.7	87.8
CNN-non-static (Kim, 2014)	48.0	87.2
CNN-multichannel (Kim, 2014)	47.4	88.1
DRNN (Irsoy and Cardie, 2014)	49.8	86.6
LSTM	45.8	86.7
Bidirectional LSTM	49.1	86.8
2-layer LSTM	47.5	85.5
2-layer Bidirectional LSTM	46.2	84.8
Constituency Tree LSTM (no tuning)	46.7	86.6
Constituency Tree LSTM	50.6	86.9

Table 2: Test set accuracies on the Stanford Sentiment Treebank. **Fine-grained:** 5-class sentiment classification. **Binary:** positive/negative sentiment classification. We give results for Tree-LSTM models with and without fine-tuning of word representations.

Sec. 4.2. For the similarity prediction network (Eqs. 15) we use a hidden layer of size 50. We compare two Tree-LSTM architectures for composing sentence representations: the Child-Sum Tree-LSTM architecture (Sec. 3.1) on dependency trees (Chen and Manning, 2014) and the Binary Tree-LSTM (Sec. 3.2) on binarized constituency trees (Klein and Manning, 2003).

5.3 Hyperparameters and Training Details

The hyperparameters for our models were tuned on the development set for each task.

We initialized our word representations using publicly available 300-dimensional Glove vectors (Pennington et al., 2014). For the sentiment classification task, word representations were fine-tuned during training with a learning rate of 0.1; no fine-tuning was performed for the semantic relatedness task.

Our models were trained using AdaGrad (Duchi et al., 2011) with a learning rate of 0.05 and a minibatch size of 25. The model parameters were regularized with a per-minibatch L2 regularization strength of 10^{-4} . The sentiment classifier was additionally regularized using dropout (Hinton et al., 2012).

6 Results

6.1 Sentiment Classification

Our results are summarized in Table 2. As was the case with the convolutional neural network model

Method	r	ρ	MSE
Mean vectors	0.8046	0.7294	0.3595
DT-RNN (Socher et al., 2014)	0.7863	0.7305	0.3983
SDT-RNN (Socher et al., 2014)	0.7886	0.7280	0.3859
Illinois-LH (Lai and Hockenmaier, 2014)	0.7993	0.7538	0.3692
UNAL-NLP (Jimenez et al., 2014)	0.8070	0.7489	0.3550
Meaning Factory (Bjerva et al., 2014)	0.8268	0.7721	0.3224
ECNU (Zhao et al., 2014)	0.8414	_	-
LSTM	0.8477	0.7921	0.2949
Bidirectional LSTM	0.8522	0.7952	0.2850
2-layer LSTM	0.8411	0.7849	0.2980
2-layer Bidirectional LSTM	0.8488	0.7926	0.2893
Constituency Tree LSTM	0.8491	0.7873	0.2852
Dependency Tree LSTM	0.8627	0.8032	0.2635

Table 3: Test set results on the SICK semantic relatedness subtask. The evaluation metrics are Pearson's r, Spearman's ρ , and mean squared error. Results are grouped as follows: (1) Our own baselines; (2) SemEval 2014 submissions; (3) Sequential LSTM variants.

described by Kim (2014), we found that tuning word representations yielded a significant boost in performance on the fine-grained classification subtask, in contrast to the minor gains observed on the binary classification subtask. This suggests that fine-tuning helps distinguish positive/negative vs. neutral, strongly positive vs. positive, and strongly negative vs. negative, as opposed to positive vs. negative in the binary case.

The Bidirectional LSTM significantly outperformed the standard LSTM on the fine-grained subtask. Note that this result is achieved without introducing any additional parameters in the LSTM transition function since the forward and backward parameters are shared. This indicates that sentence length becomes a limiting factor for the (unidirectional) LSTM on the fine-grained subtask. Somewhat surprisingly, we do not observe a corresponding improvement on the binary subtask (indeed, we achieve similar results on all our single-layer LSTM models). We conjecture that the state that needs to be retained by the network in order to make a correct binary prediction is easily preserved by both the LSTM and Bidirectional LSTM models, whereas the fine-grained case requires more complex interactions between the input word representations and the hidden state of the LSTM unit.

The Tree-LSTM over constituency trees outperforms existing systems on the fine-grained classification subtask.

6.2 Semantic Relatedness

Our results are summarized in Table 3. Following Marelli et al. (2014), we use the Pearson correlation coefficient, the Spearman correlation coefficient and mean squared error as evaluation metrics.

The mean vector baseline computes sentence representations as a mean of the representations of the constituent words. In the DT-RNN and SDT-RNN models (Socher et al., 2014), the vector representation for each node in a dependency tree is a sum over affine-transformed child vectors, followed by a nonlinearity (the SDT-RNN conditions the affine transformation on the dependency relation with the child node). For each of our baselines, including the LSTM models, we use the similarity model described in Sec. 4.2.

We also compare against four of the topperforming systems³ submitted to the SemEval 2014 semantic relatedness shared task: ECNU (Zhao et al., 2014), The Meaning Factory (Bjerva et al., 2014), UNAL-NLP (Jimenez et al., 2014), and Illinois-LH (Lai and Hockenmaier, 2014). These systems are heavily feature engineered, generally using a combination of surface form overlap features and lexical distance features derived from WordNet or the Paraphrase Database (Ganitkevitch et al., 2013).

Our LSTM models outperform these baseline systems without any additional feature engineering. On this task, the Dependency Tree LSTM model outperformed the sequential LSTM models.

7 Discussion and Qualitative Analysis

7.1 Modeling Semantic Relatedness

In Table 4, we list nearest-neighbor sentences retrieved from a 1000-sentence sample of the SICK test set. We compare the neighbors ranked by the Dependency Tree LSTM model against a baseline ranking by cosine similarity of the mean word vectors for each sentence.

We observe that the Dependency Tree LSTM model exhibits several desirable properties. Note that in the dependency parse of the second query sentence, the word "ocean" is the second-furthest

Figure 3: Fine-grained sentiment classification accuracy vs. sentence length. For each ℓ , we plot accuracy for the test set sentences with length in the window $[\ell-2,\ell+2]$. Examples in the tail of the length distribution are batched in the final window $(\ell=45)$.

Figure 4: Pearson correlations r between predicted similarities and gold ratings vs. sentence length. For each ℓ , we plot r for the pairs with mean length in the window $[\ell-2,\ell+2]$. Examples in the tail of the length distribution are batched in the final window ($\ell=18.5$).

word from the root ("waving"), with a depth of 4. Regardless, the retrieved sentences are all semantically related to the word "ocean", which indicates that the Tree-LSTM is able to both preserve and emphasize information from relatively distant nodes. Additionally, the Tree-LSTM model shows greater robustness to differences in sentence length. Given the query "two men are playing guitar", the Tree-LSTM associates the phrase "playing guitar" with the longer, related phrase "dancing and singing in front of a crowd" (note as well that there is zero token overlap between the two phrases).

7.2 Effect of Sentence Length

We investigate the effect of sentence length on the performance of our LSTM models.

³We list the strongest results we were able to find for this task; in some cases, these results are stronger than the official performance by the team on the shared task. For example, the listed result by Zhao et al. (2014) is stronger than their submitted system's Pearson correlation score of 0.8280. We do not list the StanfordNLP submission since no description of the system is provided in Marelli et al. (2014).

Ranking by mean word vector cosine similarity	Score	Ranking by Dependency Tree LSTM model

some men are playing rugby	0.88	the man is singing and playing the guitar	4.08	
two men are talking	0.87	the man is opening the guitar for donations and plays with the case	4.01	
two dogs are playing with each other	0.87	two men are dancing and singing in front of a crowd	4.00	

Table 4: Most similar sentences from a 1000-sentence sample drawn from the SICK test set. The Tree-LSTM model is able to pick up on more subtle relationships, such as that between "beach" and "ocean" in the second example.

In Fig. 4, we show the relationship between Pearson correlation with gold ratings and sentence length. The Bidirectional LSTM performs similarly to the standard LSTM for shorter inputs but significantly outperforms on longer sentence pairs. Over all windows except the last, the Dependency Tree LSTM consistently outperforms the sequential LSTM variants. The observation that the Dependency Tree LSTM outperforms even on short sentences suggests that the model benefits from the dependency information captured by the parse tree structure, rather than simply the compression of path lengths to the root.

We observe a similar outperformance by the Tree-LSTM on classifying the sentiment of shorter sentences (Fig. 3). Surprisingly, the Bidirectional LSTM also improves on the standard LSTM score in this short-sentence regime; this is perhaps attributable to the fact that the Bidirectional LSTM sentence representation has twice the dimensionality of that of the standard LSTM.

8 Related Work

Distributed representations of words (Rumelhart et al., 1988; Collobert et al., 2011; Turian et al., 2010; Huang et al., 2012; Mikolov et al., 2013; Pennington et al., 2014) have found wide applicability in a variety of NLP tasks. Following this success, there has been substantial interest in the area of learning distributed phrase and sentence representations (Mitchell and Lapata, 2010; Yessenalina and Cardie, 2011; Grefenstette et al., 2013; Mikolov et al., 2013), as well as distributed

representations of longer bodies of text such as paragraphs and documents (Srivastava et al., 2013; Le and Mikolov, 2014).

Our approach builds on recursive neural networks (Goller and Kuchler, 1996; Socher et al., 2011), which we subsequently abbreviate as Tree-RNNs in order to avoid confusion with recurrent neural networks. Under the Tree-RNN framework, the vectorial representation associated with each node of a tree is composed as a function of the vectors corresponding to the children of the node. The choice of composition function gives rise to numerous variants of this basic framework. Tree-RNNs have been used to parse images of natural scenes (Socher et al., 2011), compose phrase representations from word vectors (Socher et al., 2012), and classify the sentiment polarity of sentences (Socher et al., 2013).

9 Conclusion

In this paper, we introduced a generalization of LSTMs to tree-structured network topologies. The Tree-LSTM architecture can be applied to trees with arbitrary branching factor. We demonstrated the effectiveness of the Tree-LSTM by applying the architecture in two tasks: semantic relatedness and sentiment classification, outperforming existing systems on both. Controlling for model dimensionality, we demonstrated that Tree-LSTM models are able to outperform their sequential counterparts. Our results suggest further lines of work in characterizing the differences between sequential and tree-structured models.
